Abstract

The Internal Revenue Service periodically conducts complex surveys to measure the prefiling and filing burden of individual taxpayers in response to the requirements of the U.S. federal tax system. The sample design for the survey needs to balance three major objectives. The first is to ensure a sufficient number of respondents within and across strata to meet the needs of the modeling of compliance burden. The second is that it must be efficient so that the estimates are reliable. The third is to facilitate the comparisons between the current year study and the previous study. An iterative procedure for a stratified random sample design is proposed to search for the optimal sample allocation. The proposed procedure utilizes the optimality in the Neyman allocation method, and incorporates the minimum sample size requirements for modeling and different nonresponse rates across strata. Our adjustment on the Neyman allocation causes loss of efficiency for descriptive analysis, but such loss of efficiency is minimized so that the estimates still meet the precision requirements. Furthermore, such loss is well compensated by the gains in modeling and analytical capabilities.

Key words: Complex survey sample design, Neyman allocation, Nonresponse rate, Sample size, Optimality, Sensitivity analysis

1. Introduction

The Internal Revenue Service periodically conducts complex surveys to measure the prefiling and filing burden of individual taxpayers in response to the requirements of the U.S. federal tax system. One of the challenges of this type of research is incorporating what one learns from one study in the design of the subsequent study while maintaining comparability between the studies. Our sample design specifications are developed to balance three issues. The first and most important is to ensure that there are a sufficient number of cases to meet the needs of the modeling tool to identify the determinants of burden, both within and across stratum. The second is that it must be efficient in the way the sample is distributed so that estimates from the sample are reliable (i.e., meet confidence interval range requirements). The third is that the design should facilitate the comparisons between the studies. This paper discusses our approach to the sample design for Individual Taxpayer Burden (ITB) TY2010² survey embedding the previous TY2007 survey sample design for comparability.

¹ The views expressed are those of the authors and not the official positions of the Internal Revenue Service.

² TY2010 refers to tax year 2010. We will use this notation throughout the paper.

An iterative procedure for a stratified random sample design is proposed to search for the optimal sample allocation. The proposed procedure utilizes the optimality in the Neyman allocation method, and incorporates the minimum sample size requirements for modeling and different nonresponse rates across strata. Our adjustment on the Neyman allocation causes loss of efficiency for descriptive analysis, but such loss of efficiency is minimized so that the estimates still meet the precision requirements. Furthermore, such loss is well compensated by the gains in modeling and analytical capabilities.

To make the study of ITB TY2010 survey comparable with the one of TY2007 survey, we continue to use the same design variable, total monetized burden, the same stratified random sampling approach, and the same stratification variables that were used in the TY 2007 study.³ The Neyman allocation method was used to determine the optimal sample size for each stratum subject to the total sample size of 15,000 in the sample design for the ITB TY2007 survey. It aimed to minimize the variance of the estimated mean burden, but it left several strata with too few observations to model. A common rule of thumb is that a sample must include at least 10 or 15 observations per independent variable in a regression model (Stevens, 2002; Bartlett et al., 2001). We choose 15 to be conservative. The expected number of independent variables is 15, so the minimum expected number of complete responses for modeling is 225 for each stratum.

Our objective is to minimize the variance of the estimated mean burden constrained on this minimum expected number of complete responses for modeling, with response rate incorporated. The total sample size increases to 20,000 in the ITB TY2010 survey. We start with the same total sample size of 15,000 as in TY2007, considering this as our base sample. The remaining 5,000 is the reserved sample to make any adjustments for the purposes of modeling and increasing the precision of the estimate. An iterative procedure is used to search for our optimal sample allocation. The final allocation with key inputs is shown in Table 1. This design results in an overall CV of 1.01%, less than 2%, the general requirement on precision.

³ This approach is discussed in further detail in Brick, *et al*, 2009 and Contos, *et al*, 2010.

 Table 1 Sample allocation for ITB TY2010 survey

2. Iterative Procedure for Sample Allocation

TY2010 population counts within each stratum are projected based on TY2009 population counts and the projected growth rates. TY2007 survey data are used to estimate the mean, standard deviation, and item response rate of monetized burden for each stratum. With these inputs, we are able to determine the sample allocation as follows.

2.1 Step 1

The adjustment procedure in Step 1 is shown in Table 2. The Neyman allocation method is first applied to the base sample of 15,000, the sample size of the TY2007 ITB survey sample. The expected numbers of respondents are obtained for each stratum according to the estimated item response rates⁴. We compare these numbers with 225, the minimum sample required to model each stratum. Nine strata are identified that do not contain enough respondents. The sample sizes for these strata are adjusted so that the expected numbers of respondents that are highlighted in Table 2 equal 225, while the sample sizes for the remaining strata maintain the Neyman allocation. This procedure results in a total sample size of 18,540, indicating that we have more sample to be allocated to the base sample to increase the precision of the estimate.

⁴ The estimated item response rates are the lower bounds of the 99% Wilson Score confidence intervals in TY2007, adjusted for the overall expected lower bound of the response rate at 40% in TY2010.

| Monetized Burden | Ney- | Est. Item | Expected | Minimum | Adjusted |

Table 2: Adjusted Allocation Step 1: Adjustment of Neyman Allocation for Modeling

2.2 Step 2

In Step 2, we determine the maximum sample size for base sample for the Neyman allocation, given the nine strata identified for further adjustment in the Step 1. The following inequality (1) is used to find the maximum sample size for base sample.

$$n_{b} \frac{\sum_{h \in A} N_{h} S_{h}}{\sum_{h \in H} N_{h} S_{h}} + (20,000 - n_{b}) \ge 5,600, \qquad (1)$$

Where n_b is the total base sample size, N_h and S_h are the population count and standard deviation for stratum h, $A = strata\{1,21,22,23,24,25,31,32,35\}$, H is the entire set of all strata. The minimum total sample size is 5,600 for all nine strata identified in Step 1 (the sum of the highlighted numbers in the last column of Table 2).

The first component on the left-hand side of inequality (1), $n_b \frac{\sum_{h \in A} N_h S_h}{\sum_{h \in H} N_h S_h}$, represents the

sum of the sample sizes for all nine strata in A from the base sample, due to the Neyman allocation. The second component, $20,000 - n_b$, represents the sum of the sample sizes for all nine strata from the reserved sample to adjust for modeling. We solve Inequality (1) for n_b and $n_b \le 16,693$.

The adjustment procedure in Step 2 is shown in Table 3. The Neyman allocation for the base sample of size 16,693 is calculated, and then the adjustment procedure from Step 1 is repeated. Step 2 results in a total sample size of 20,008. This is because the number of strata to be adjusted is reduced from nine to eight since the base sample size increases in Step 2. Specifically, the sample size in stratum 32 that results from Neyman allocation becomes sufficient for modeling and does not need to be adjusted. The value for $n_b = 16,693$ is obtained assuming that nine strata need to be adjusted; however the result shows only eight strata need to be adjusted, indicating that this "non-matching" or "non-steady" state requires another iteration.

| Monetized | Neyman | Estimated | Expected | Minimum | Adjusted |

Table 3: Adjusted Allocation Step 2

2.3 Step 3

In Step 3, we adjust the sample size for base sample so that the final total sample size reaches exactly 20,000, given the eight strata identified for adjustment in Step 2. Inequality (2) is used to find the sample size for base sample.

$$n_{b} \frac{\sum_{h \in B} N_{h} S_{h}}{\sum_{h \in H} N_{h} S_{h}} + (20,000 - n_{b}) \ge 4,988, \qquad (2)$$

Where, $B = strata\{11,21,22,23,24,25,31,32\}$. 4,988 is the minimum total sample size for all eight strata identified in Step 2--the sum of the highlighted numbers in the last column of Table 3. We solve Inequality (2) for n_b and $n_b \le 16,684$. We start with the base sample of 16,684 for the Neyman Allocation, and repeat the same adjustment procedure as in Step 2. The number of strata requiring adjustment remains the same in this round, implying that we have reached a "steady state" and the resulting total sample size reaches the exact 20,000 as required. The adjustment procedure is shown in Table 4.

| Table 4: Adjusted | 1 | 1 | | 30.1 | |

Table 4: Adjusted Allocation Step 3: Final Allocation.

In summary, the allocation adjustment procedure described above maximizes the optimality in the Neyman allocation method subject to the minimum sample size necessary for modeling within each stratum, while incorporating response rate. As we can also see, the adjustment for modeling in the above iterative procedure is minimized

subject to the total sample size of 20,000. Even though we expect a sacrifice in precision due to adjustment of the Neyman allocation, this sacrifice has been minimized.

3. Evaluation of the Proposed Sample Design

Table 5 presents a comparison between the final design (Design I) and the Neyman allocation of 20,000 without any adjustment (Design II). The expected number of respondents from our design satisfies the minimum sample size for modeling within each stratum, while the expected numbers of respondents for seven strata from the Neyman allocation without any adjustment are far less than the minimum sample size.

The overall CV from the Neyman allocation without any adjustment is 0.95%, while the overall CV from our design is 1.01%. The precision in our design decreases, as expected, which is a trade-off for incorporating modeling and response rate. However, our overall CV is still comparable with the overall CV from the Neyman allocation. Such sacrifice in precision is minor and is well compensated by the gains in modeling. The overall CV based on the expected number of respondents is 1.62% from our design, and again it is comparable with the corresponding CV of 1.53% from the Neyman allocation.

Table 5: Comparisons between Two Designs:

The Neyman allocation method assumes population counts and standard deviations are both known for all strata, however in practice they are often estimates. We evaluate the projection method of the TY2010 population by comparing the actual count in TY2009 and the projected count in TY2009 using the same projection method. The average relative error rate among all the strata is 0.0037, supporting our projected counts for TY2010. However, there is not a straightforward measure to see how reliable our estimated standard deviations are. It is of interest to investigate how robust our design is to different values of population standard deviations. We obtain different sets of standard deviation estimates, and assume they represent the true population parameter values in TY2010 and the overall CVs can be calculated based on these estimates and our sample design. Table 6 shows that our proposed sample design can still satisfy the precision requirement even when the population standard deviations are mis-specified. Therefore, our design is robust to different estimates on population standard deviations.

 Table 6: Robustness of the proposed sample design to different values of standard deviations

- Std. Dev. I: estimates used in our final design
- Std. Dev. II: estimates using multiple imputations
- Std. Dev. III: estimates including outliers
- Std. Dev. IV: estimates excluding the observations above the 99th percentile Std. Dev. V: estimates from ITB TY99/00 survey

| Overall CV | 1.01% | 1.40% | 1.29% | 0.79% | 1.02% |

Finally, we consider the implications of our proposed design on the other three relevant variables, total money, total monetized time, and total time with respect to both precision

of the estimates and modeling. Since the estimated item response rates for these three variables are almost identical to the ones for total monetized burden, immediately it follows that the expected number of respondents from our design will satisfy the minimum sample size requirement for modeling these three variables. Table 7 shows the overall CV for each of the three variables based on our design, compared with the CV from the Neyman allocation for each variable separately.

As shown in Tables 7-1, 7-2, and 7-3, although our design based on the total monetized burden still can satisfy the modeling of all three variables, the sacrifice in precision is greater comparing the Neyman allocation with each variable as the design variable. This indicates that a more advanced algorithm is needed if we want to simultaneously estimate and model total money, total monetized time, and total time. We expect that our proposed design will provide sufficient responses in the various strata to support further refinements in future designs. However, the Neyman allocation without any adjustment for any of the three variables results in modeling issues.

4. Conclusions

An iterative procedure is proposed to search for the optimal sample allocation to optimize the Neyman allocation subject to the minimum sample size for modeling purposes, with response rates incorporated.

On one hand, any adjustment on the Neyman allocation may cause loss of efficiency; on the other hand, the Neyman allocation without any adjustment will leave us with some strata with too few observations to model. Our proposed sample allocation procedure shows that such loss of efficiency can be minimized with appropriate adjustment; moreover, it can be well compensated by the gains from modeling and the ability to conduct valid predictive analysis.

Contemporary surveys often serve multiple purposes—both descriptive and predictive analyses. How to balance between the objectives to achieve a certain level of precision on the estimates and to conduct valid predictive analysis requires more theoretical development. Our future research will extend the approach described here. We are also interested in exploring the optimal allocation algorithm when the objective of the survey is to estimate and model multiple variables simultaneously.

Finally, Neyman allocation is often criticized because it ignores possible different response rates across strata. When response rates are quite different across different strata, the objective function is to minimize the variance of the mean estimate based on the respondents, and the sample size can be calculated from the number of respondents and response rate. We expect that a more rigorous optimization procedure reflecting these response rate differences will further improve the performance of the sample design.
